## Wastewater PES

Polyester textile:  
~ 90 % particles,  
~ 10 % fibers

## Textile Surface

# Chemical Identification of Fiber Debris from Blended Fabrics

50/50% Polyester/Cotton

65/35% Polyester/Cotton

# ***Summary***

- Quantification of total debris = filtration is fine
- But filtration collects **ALL debris**
- Full filtered debris consists of ~90% particles and 10% fibers (acc. to our and others current data)
- This results in a much higher shed weight (approx. 90% is not genuine fiber debris)
- Quantification of microfiber debris = visual analysis (i.e. DIA, SEM) is the only option

# ***Funding Acknowledgement***

We thank the Textile Research Council for their financial support for the AiF-project 19219 N, which was provided using funds from the German Federal Ministry of Economics & Technology (BMWi) via the Federation of Industrial Research Associations AIF as part of the program to support "Industrial Community Research & Development" (IGF) following an Order by the German Federal Parliament.

Nowack et al.:

Ecotoxicological risk assessment of microplastics

<https://setac.onlinelibrary.wiley.com/doi/full/10.1002/etc.4323>

“Overall, the average risk characterization ratio is several orders of magnitude below 1, indicating no immediate risk to the environment (in the EU). However, a small risk cannot be excluded, especially in Asia, where there is a certain overlap of the exposure and hazard probability distributions.”

### Abstract

Microplastics have been detected in freshwaters all over the world in almost all samples, and ecotoxicological studies have shown adverse effects of microplastics on organisms. However, no risk assessment of microplastics has been performed specifically in freshwater so far. The aim of the present study was therefore to review all exposure and ecotoxicity data available for microplastics in freshwaters and to perform a preliminary probabilistic risk assessment. The exposure probability distribution was based on 391 concentrations measured in Asia, Europe, and North America. Because exposure data are mainly available in particle number-based metrics but results from hazard studies are mostly mass-based, the hazard results were converted into particle number concentrations. A statistical analysis of the hazard data showed that there was no significant influence of particle shape or type of polymer on the no-observed-effect concentration. The predicted-no-effect concentration (PNEC) was calculated as the fifth percentile of the probabilistic species sensitivity distribution, based on 53 values from 14 freshwater species, to have a mode of  $7.4 \times 10^5$  particles  $\cdot$  m<sup>-3</sup> (25th and 75th quantiles of
